Abstract. Artifact reduction in electroencephalogram (EEG) signals is usually necessary to carry out data analysis appropriately. Despite the large amount of denoising techniques available with a multichannel setup, there is a lack of efficient algorithms that remove (not only detect) blink-artifacts from a single channel EEG, which is of interest in many clinical and research applications. This paper describes and evaluates the Iterative Template Matching and Suppression (ITMS), a new method proposed for detecting and suppressing the artifact associated with the blink activity from a single channel EEG. The approach of ITMS consists of (a) an iterative process in which blink-events are detected and the blink-artifact waveform of the analyzed subject is estimated, (b) generation of a signal modeling the blink-artifact, and (c) suppression of this signal from the raw EEG. The performance of ITMS is compared with the Multi-window Summation of Derivatives within a Window (MSDW) technique using both synthesized and real EEG data. Results suggest that ITMS presents an adequate performance in detecting and suppressing blink-artifacts from a single channel EEG. When applied to the analysis of Cortical Auditory Evoked Potentials (CAEPs), ITMS provides a significant quality improvement in the resulting responses. The proposed ITMS algorithm is easy to be implemented, as can be observed in the Matlab script provided as supporting material.

Keywords: artifact removal, single channel EEG, quality enhancement, blinking, brain-computer interface (BCI) games
1. Introduction

The use of electroencephalogram (EEG) signals is nowadays very common in several research fields because of its objective and non-invasive nature [1, 2]. Some of these research fields include neuroscience [3]; evaluation of cognitive factors like attention [4], learning [5] and memory [6, 7]; linguistic development [8, 9]; and diagnosis of cognitive disorders like dyslexia [10], autism [11], and auditory processing disorder [12].

The recorded EEG signals are often contaminated by biological artifacts of different origin, such as eye-blinks, ocular movements (saccades), and muscular and cardiac activity; by non-biological factors like the amplifier noise proportional to the impedance between the electrodes and the scalp; and by electromagnetic fields induced by external sources [13]. In particular, the eye-blink artifact is among the factors that mostly degrades the quality of the EEG signals, especially in the frontal channels [14]. Therefore, the use of signal processing techniques that compensate for this undesired effect is usually necessary.

Blink-artifact removal has been approached from many different perspectives. A comprehensive review of EEG artifact removal techniques can be found in [15]. According to this review, the most used techniques reported in the literature are based on electrooculogram (EOG) subtraction, adaptive filtering, and independent component analysis (ICA). The approach of EOG subtraction methods consists of subtracting from each analyzed EEG channel a proportion of one or more reference EOG channels containing the blink-artifacts (usually vertical and horizontal; and also radial for optimal performance) [16, 17]. The major disadvantages of these methods are that they require additional EOG channels as a reference, and that they do not assume bidirectional contamination, i.e. that the EOGs may also be ‘contaminated’ by a proportion of the signal of interest, thus part of the signal of interest in the EEG would be cancelled in the subtraction process. These methods are still considered by many authors as the ‘gold-standard’ because of their simplicity, good performance, and low computational load [18, 19, 20].

Adaptive filtering methods consist of designing the filter parameters that minimize the error between the contaminated and the desired (free of artifact) EEG. In these methods, the filter generates a signal correlated with the artifact, which is then subtracted from the contaminated EEG [21]. These methods also require additional EOG channels as a reference to operate [22].

ICA is based on the linear mixture concept, in which the recorded EEG and EOG channels are modeled as the combination of contributions from different brain and artifact sources [23]. Artifact rejection with ICA involves a complex mathematical process consisting of (a) decomposing the EEG channels into statistically independent components, (b) selecting the components associated with the eye-blink artifact, and (c) recomposing the EEG signals without the selected artifact components [24, 25]. Although ICA can be implemented in a single-channel configuration, the optimal performance of this technique requires the use of several EEG channels [26]. In the
last decade, ICA has become very popular because of its performance [27, 28, 29], and in part, because of its easy implementation as it has been integrated into open-access signal processing toolboxes like EEGLab [30]. However, there is an ongoing debate about the quality of blink-artifact correction when decomposing and recomposing the EEG signals into independent components [18, 31, 32, 33].

In contrast to the large number of techniques available in multichannel applications, there has been little research in developing signal processing techniques to deal with the blink-artifact in single-channel EEG applications. These applications are nowadays very common in the clinic, e.g. estimating hearing thresholds with cortical auditory evoked potentials (CAEPs) [34]; as well as in an increasing number of brain-computer interface (BCI) applications in the fields of research and games, derived from a new generation of low-cost and portable EEG recording devices characterized by using a low number of channels and no access to EOG data [35, 36, 37].

The most relevant techniques to detect blink-events in single-channel EEG applications are based on amplitude-threshold, template matching, and derivatives. Amplitude-threshold based techniques consist of evaluating whether the maximum amplitude within an epoch (i.e., EEG segment containing the signal of interest and noise) exceeds a threshold, which can be set in advance by the user or automatically considering the EEG amplitude distribution [38, 39]. These methods are relatively easy to implement, but they present limitations such as (a) low accuracy, since they cannot distinguish blink-events from other high-amplitude artifacts, e.g. muscular activity or jaw movements [40]; (b) they cannot define the blink-artifact morphology or the EEG interval in which the blink-artifact occurs [41]; and (c) blink-events with the main peak component outside the limits of the epochs cannot be detected [42].

Template matching is a well-known signal processing technique for pattern recognition, which is currently being used in a variety of fields such as image processing [43, 44], signature recognition [45], stock technical analysis [46, 47], automatic classification of seismic activity [48], etc. Methods based on template matching essentially provide a distance representing the similarity between a test signal and a predefined waveform (template). A threshold must be specified for detection purposes. Template matching has been previously used in detecting blink-events in single-channel EEG applications [49, 50]. The major challenges of these methods are (a) the definition of the template, because the performance of the method would be affected if the blink-artifact morphology of a test subject does not match the template; and (b) the definition of the threshold. Both papers solve these issues by asking the user to set the threshold manually and by using a library consisting of a number of templates of different morphology. These solutions present the inconveniences of requiring expertise from the user, which makes the method inconsistent worldwide; and dependent on the library of templates selection.

A third approach for blink-artifact detection is based on the use of derivatives. These methods assume that the blink-artifacts present a triangular-shape morphology, and aim to detect abrupt changes by analyzing the derivative function of the raw
EEG [51]. The multi-window summation of derivatives within a window (MSDW) technique requires the user to set a threshold manually, but it does not require a database of templates and is able to estimate the EEG intervals in which the blink-artifacts occur. MSDW presents better accuracy in detecting epochs containing blink-events compared to the amplitude-threshold and the traditional template matching approaches.

The major limitation of the aforementioned methods is that they allow detection, but not correction, of blink-artifacts. These methods have been typically used to detect and reject epochs contaminated with blink-artifacts, which eventually leads to the undesired loss of useful data [42, 16]. Unfortunately, methods able to detect and correct blink-artifacts from a single channel EEG are scarce.

The objective of this paper is to describe and evaluate a novel approach for detection and suppression of blink-artifacts in a single-channel EEG signal. The procedure is based on Iterative Template Matching and Suppression (ITMS). First, detection of blink-events is carried out by an iterative implementation of template matching, using a predefined blink-artifact template in the first iteration, and a blink-artifact waveform estimated from the test subject in the following iterations. Second, a blink-artifact signal is modeled considering the blink-artifact waveform of the subject and the positions and amplitudes of the detected blink-events. Finally, the signal modeling the blink-artifact is subtracted from the raw EEG to obtain the denoised EEG.

The performance of the ITMS method is compared with the MSDW technique in terms of both blink-artifact detection and suppression. A software script programmed in Matlab (The Mathworks, Inc., Natick, MA) that implements the ITMS algorithm is available as supplementary material (appendix A).

2. Iterative Template Matching and Suppression (ITMS)

This section describes the mathematical formulation for the Iterative Template Matching and Suppression (ITMS) algorithm, which includes the blink-artifact estimation and its suppression from the recorded EEG. The ITMS method assumes that the recorded EEG \( y(n) \) is the summation of three uncorrelated processes: the blink-artifact \( x_{\text{blink}}(n) \), the signal of interest \( x_{\text{signal}}(n) \), and the noise \( x_{\text{noise}}(n) \) associated with the recording procedure,

\[
y(n) = x_{\text{blink}}(n) + x_{\text{signal}}(n) + x_{\text{noise}}(n),
\]

where \( n = 0, \ldots, N - 1 \), and \( N \) is the total number of samples in the EEG. The objective of ITMS is to obtain an estimate of the blink-artifact process \( \tilde{x}_{\text{blink}}(n) \) in order to provide an enhanced EEG in which the blink-artifact is suppressed.

The blink process is assumed to be linear and time-invariant (LTI), i.e. each blink-event produces an additive artifact with the same template (even though with unknown amplitude), and the blink-artifact is the sum of the artifact associated with each individual event. The blink-artifact can therefore be modeled as the convolution of a blink-artifact template \( h(n) \) (\( n = 0, \ldots, L - 1 \)) with \( K \) impulses (at positions \( m_k \))
and with amplitudes $A_k$) representing the blink-events

$$\hat{x}_{\text{blink}}(n) = h(n) \ast \sum_{k=1}^{K} A_k \delta(n - m_k) = \sum_{k=1}^{K} A_k \cdot h(n - m_k),$$

where $L$ is the number of samples of the blink-artifact template, $K$ is the number of blink-events, $\ast$ represents the convolution operator and $\delta(n)$ is the unitary impulse at $n = 0$. As a final assumption, the amplitude of the blink-artifact is accepted to be relatively large compared with the other signals, which is consistent with the artifacts usually observed in EEG recordings.

ITMS estimates the blink-artifact (i.e. the template $h(n)$, and the parameters $A_k$, $m_k$ describing the blink-events) through an iterative process, in which $h(n)$ is initialized with a predefined template $h_0(n)$. The estimation of the blink-artifact is iteratively performed by (a) detecting the blink-events (through cross-correlation of the recorded EEG with the template representing the blink-artifact) and (b) re-estimation of the blink-artifact template (through averaging the EEG portions corresponding to the blink-events). After the convergence of the iterative process, the template $h(n)$ and the blink-event parameters ($m_k$ and $A_k$) provide the blink-artifact estimate $\hat{x}_{\text{blink}}(n)$, which can be subtracted from the EEG.

Figure 1 shows a flowchart of the ITMS algorithm. At the first iteration, $h(n)$ is initialized with $h_0(n)$. At each iteration, the blink-events are detected by analyzing the local maxima of the cross-correlation function of the recorded EEG $y(n)$ and the current template $h(n)$. The detected blink-events at positions $m_k$ are used to average the portions of EEG associated to each blink-event in order to re-estimate the blink template $h(n)$. This way, at each new iteration a better detection of the blink-events

---

**Figure 1.** Iterative Template Matching and Suppression algorithm flowchart.
provides a better estimation of the blink-template. After $I$ iterations, the template $h(n)$ and the positions of the blink-events $m_k$ are used for estimating the amplitudes of the blink-events $A_k$. Finally, the template and the blink-event parameters ($h(n)$, $m_k$ and $A_k$) are used for estimating the blink-artifact $x_{\text{blink}}(n)$ and for suppressing it from the EEG.

This procedure provides an estimation of the blink-template specifically adapted to the subject and to the recording conditions (i.e. electrode impedances, specific location of the recording electrodes, etc.). As a consequence, the blink-artifact will be optimally suppressed from the EEG. The processes involved in the proposed method are described in detail below.

2.1. Blink-events detection

At each iteration $i$, detection of blink-events $m_k$ is carried out through the cross-correlation between the EEG $y(n)$ and the current blink-template $h(n)$. The cross-correlation can be implemented by filtering $y(n)$ with the matched-filter (consisting in the time-reversed version of $h(n)$) [52]. Since every blink-event produces a local maximum in the matched-filter output, the local maxima of this function are candidates to be categorized as blink-events. The matched-filter output can be obtained as,

$$z(n) = y(n) * h(L - 1 - n)$$

and it provides the cross-correlation between $y(n)$ and $h(n)$ with a delay when a causal implementation of the matched-filter is applied (i.e. there is a delay of $L - 1$ samples between each impulse generating an artifact and the corresponding local maximum in $z(n)$, since $h(L - 1 - n)$ is used instead of $h(-n)$).

Let $Z_{0j}$ and $m_{0j}$ be, respectively, the amplitudes and positions of the local maxima in $z(n)$,

$$Z_{0j} = z(m_{0j}) \quad \forall \ m_{0j} \text{ verifying that } z(m_{0j}) > z(m_{0j} \pm 1)$$

where $j = 1, \ldots, J$, and $J$ is the total number of local maxima in $z(n)$. On one hand, the blink-events generate local maxima with large (and positive) amplitudes in the cross-correlation function, according to the amplitude distribution of the blink-events. On the other hand, noise and other uncorrelated signals (with waveforms different to that of the template) produce a large number of random local maxima with smaller amplitudes. Therefore, the histogram of the local maxima $\{Z_{0j}\}$ is expected to show a large and narrow Gaussian mode centered at zero (corresponding to the local maxima associated to noise and other uncorrelated signals) and a wider mode with larger amplitudes (corresponding to the blink-events).

Categorization of local maxima candidates as blink-events or uncorrelated signals is carried out through the analysis of the histogram of local maxima. Following the approach proposed by Kim and McNames (2007) for automatic spike detection in extracellular neural recordings [53], the histogram is smoothed with a Gaussian kernel (with a 15% of the interquartile interval as bandwidth); the maximum of the smoothed
histogram is associated to the mode corresponding to the uncorrelated signals, and the following minimum of the smoothed histogram (on the side of positive amplitudes) is used as threshold, $T$. The detected blink-events correspond to those local maxima $Z_k$ with amplitude greater than the threshold,

$$Z_k = z(m_{0k}) \quad \forall m_{0k}$$

verifying that

$$\begin{cases} z(m_{0k}) > z(m_{0k} \pm 1) \\ z(m_{0k}) > T \end{cases}$$

and the beginning of each detected blink-event is obtained as:

$$m_k = m_{0k} - L + 1$$

by compensating the delay of $L - 1$ samples from the corresponding local maxima at $m_{0k}$, where $k = 1, \ldots, K$, and $K$ is the number of detected blink-events. At the end of this section, the procedure for detecting the blink-events is illustrated with an example.

2.2. Estimation of the blink-artifact template

The template $h(l)$ (with $l = 0, \ldots, L - 1$) is estimated from the EEG $y(n)$ and the positions of the detected blink-events $m_k$. In order to estimate the template, the segments of the EEG corresponding to the detected blink-events are organized in a $K \times L$ matrix,

$$Y = [y_{k,l}] \quad y_{k,l} = y(m_k + l).$$

In an hypothetical situation with accurate detection (each $m_k$ corresponds to a blink-event) the estimation would be carried out by a simple average of the EEG segments (i.e. by synchronized averaging),

$$h(l) = \frac{1}{K} \sum_{k=1}^{K} y_{k,l}.$$  

However, detection errors (for example: some low amplitude peaks corresponds to noise; high amplitude impulsive noise produces high amplitude local maxima in the cross correlation) would result in inaccurate estimates of $h(l)$ (and therefore in an inaccurate detection of the blink-events in the iterative procedure). In order to prevent this problem, the template is estimated as a weighted average:

$$h_w(l) = \sum_{k=1}^{K} w_k \cdot y_{k,l}$$

where $w_k$ are weights included to modulate the contribution of each sample to the average. In this work, the weights originate from a Hamming window:

$$w_k = \begin{cases} 0 & \text{if } r_l(k) < 0.25K \text{ or } r_l(k) > 0.75K \\ 0.54 - 0.46 \cos \left( 4\pi \frac{r_l(k) - 0.25K}{K-1} \right) & \text{otherwise} \end{cases}$$

where $r_l(k)$ is the rank of $y_{k,l}$ in the set \{y_{1,l}, y_{2,l}, \ldots, y_{K,l}\} (i.e. the position of $y_{k,l}$ after sorting them). This way, the estimation of the impulsive response $h(l)$ is a weighted average. Despite the symmetry of the Hamming window, the weights $w_k$ are the same when sorting in ascending or descending order.
average where all those values outside the percentiles 25-75 do not contribute, and those between these percentiles do contribute with a weight modulated by a Hamming window (the contribution of the median is maximum), and therefore the estimation of the impulsive response shares the advantages of a median-based estimation (small influence from outliers [54]) and those of a mean-based estimation (a group of samples contributes to the estimation). The mean of the resulting signal is subtracted, 20 Hz low-pass filtered (4th order, Butterworth) and a linear fade-in/out of 200 ms is applied in order to remove DC level, smooth the signal and avoid discontinuities at the beginning and at the end of the template. Finally, the estimated impulsive response is normalized, 

\[ h_l = \frac{h_w'(l)}{\sqrt{\sum_{l=0}^{L-1} h_w'^2(l)}} \]  

where \( h_w'(l) \) is the demeaned, low-pass filtered and faded-in/out version of \( h_w(l) \).

The initial template \( h_0(n) \) used in this study was obtained by averaging and normalizing the blink-artifact waveforms identified in a cohort of 14 normal hearing adults (8 males, 43.26 ± 7.18 yr). The detailed procedure that we followed to obtain \( h_0(n) \) is provided as supplementary material (appendix B). According to the morphology of the blink-artifact, the duration of the template was set to 1400 ms.

### 2.3. Blink-artifact amplitudes

The amplitudes \( A_k \) of each blink-event are estimated from the EEG \( y(n) \), the blink-artifact template \( h(n) \) and the positions \( m_k \) of the identified blink-events. Taking into account the model of the EEG in equation (1), and since the matched-filter enhances the blink-events and attenuates the contribution of the other signals, the matched-filter output can be approximated as:

\[ z(n) \approx x_{\text{blink}}(n) \ast h(L - 1 - n) = \sum_{k=1}^{K} A_k h(n - m_k) \ast h(L - 1 - n) \]  

From the definition and properties of the autocorrelation function \( R_h(n) \) of the impulsive response,

\[ R_h(n) = h(n) \ast h(-n) \quad h(n - m) \ast h(-n) = R_h(n - m) \]  

the matched-filter output can be approximated as:

\[ z(n) \approx \sum_{k=1}^{K} A_k R_h(n - m_k - L + 1) \]  

Finally, if the matched-filter output is evaluated at the local maxima associated with the blink events, we obtain \( K \) equations (one for each detected blink-event):

\[ Z_k = z(m_0k) = z(m_k + L - 1) \approx \sum_{k'=1}^{K} A_{k'} R_h(m_k - m_{k'}) \]  

If the blink-events do not overlap (i.e. the minimum distance between successive \( m_k \) positions is greater than \( L \)), the term \( R_h(m_k - m_{k'}) \) is null when \( k \neq k' \), and
equal to 1 when \( k = k' \) (because \( h(n) \) is normalized). In that case, the amplitudes could be directly estimated as the value of the matched-filter output evaluated at the corresponding maximum (\( A_k = Z_k \)). However, when the blink-events are overlapped, the local maxima of the matched-filter output are affected by the overlapping events and the \( K \) equations in (15) should be worked out in order to estimate the amplitudes. These \( K \) equations can be written in matrix form:

\[
Z \approx R_h \cdot A
\]

where \( Z \) is a \( K \)-elements vector including the local maxima of the matched-filter output for each detected blink-event, \( A \) is a \( K \)-elements vector with the amplitudes of the blink-events to be estimated, and \( R_h \) is a \( K \times K \) matrix including the autocorrelation function evaluated at \( (m_k - m_{k'}) \) for each \( k, k' \) between 1 and \( K \):

\[
R_h(k, k') = R_h(m_k - m_{k'})
\]

Note that \( R_h \) is a quasi-diagonal symmetrical matrix, with ones in the main diagonal, values between -1 and 1 outside the diagonal, and null values for non-overlapping events (i.e. when \( |m_k - m_{k'}| > L \)). Since overlapping of blink-events is expected to affect only a few adjacent events, only a few diagonals (in addition to the main diagonal) are expected to be non-null. Therefore, despite the size of the \( R_h \) matrix, inverting it does not require a large computational load and the estimation of the amplitudes can easily be obtained as:

\[
A = (R_h)^{-1} \cdot Z
\]

2.4. Blink-artifact suppression

When both the blink template (described by \( h(n) \)) and the blink-events (described by \( A_k \) and \( m_k \)) are estimated, the signal describing the blink-artifact can be estimated as:

\[
\hat{x}_{\text{blink}}(n) = \sum_{k=1}^{K} A_k h(n - m_k)
\]

and the enhanced EEG can be estimated by suppressing the blink-artifact estimate:

\[
y_{\text{enhanced}}(n) = y(n) - \hat{x}_{\text{blink}}(n). \]

The performance of the ITMS method is illustrated with an example included in Figure 2. The EEG was recorded from a normal hearing adult (female, 30 yr). Figure 2.A shows a segment of an EEG, \( y(n) \), in which three blink-events can be identified (blue line). The orange line represents the matched-filter output, \( z(n) \). The delay between the blink-events and the corresponding maxima in the matched-filter output can be observed. The local maxima of \( z(n) \) (indicated with black diamonds) are blink-event candidates.

Figure 2.B shows the normalized histogram of the amplitudes of the local maxima \( (Z_{0j}) \), and the kernel-based smoothed histogram. This histogram shows a bimodal distribution with a large mode around zero, representing the signals not correlated
Figure 2. Details of the ITMS process. [A] Raw EEG (blue) and output of the matched-filter function $z(n)$ (orange). Local maxima of $z(n)$ (black diamonds) are blink-event candidates. [B] Histogram of the local maxima amplitudes ($Z_0$), and kernel based smoothed histogram. The threshold (T) that separates the noise and the blink-events distributions is represented with a green square. [C] Initial template ($h_0(n)$) and blink-artifact waveforms obtained in each iteration ($h_1(n)$ to $h_3(n)$). The total number of blink-events detected in each iteration is shown in brackets. [D] Simulation of amplitudes estimation in overlapping blink-events. [E] Suppression of the estimated blink-artifact model ($\hat{x}_{\text{blink}}$) from the raw EEG leads to an enhanced EEG.
with the blink template (noise and other signals); and a wider mode with larger amplitudes, representing the blink-events. The ITMS algorithm sets the threshold $T$ that separates these two modes as the first local minimum of the smoothed histogram after the maximum corresponding to the noise mode. The local maxima candidates are categorized as blink-events if their amplitude is greater than the threshold.

Figure 2.C shows the waveform morphology of the initial template $h_0(n)$ used in this study (thick blue line) and the blink-artifact templates estimated in the first three iterations ($h_1(n)$ to $h_3(n)$). This figure shows the fast convergence of the ITMS method.

Figure 2.D illustrates that the amplitudes $A_k$ can be estimated as the value of the corresponding local maximum $Z_k$ when the blinking-events are not overlapped, but not when they are overlapped. The top row shows three equal blink-artifact waveforms used to generate a synthesized EEG, the second signal shows the synthesized EEG $y(n)$ and the third signal is the matched-filter output $z(n)$. The first blink $x_1$ is not overlapped, and therefore $Z_1 = A_1$. However, due to the overlapping of the other two blinks, the amplitudes of the matched-filter output ($Z_2$ and $Z_3$) are different than those of the blinks ($A_2$ and $A_3$). In general, some degree of overlapping among blinks is expected and an accurate determination of the amplitudes requires an estimation using the proposed method.

Figure 2.E shows an example of a segment of an EEG $y(n)$ where a number of blink-events can be identified (top), the estimated blink-artifact $\hat{x}_{\text{blink}}(n)$ (middle), and the enhanced EEG in which the blink-artifact has been suppressed (bottom). The modified segments in the EEG are shown in red color in the $y_{\text{enhanced}}(n)$ signal. This figure shows that the portions of the EEG with no detected blink-events remain unaltered.

The experimental material presented in the assessment section, along with the example shown in figure 2, provide the verification of the initial assumptions: for a given EEG recording, the blink-artifact can be modeled as a LTI process, i.e. the blink-artifact template is stable; the amplitude of the blinking-events fluctuates in a relatively wide range; and the amplitude of the blinking-artifact is relatively large compared with the other signals in the EEG.

3. Assessment

The performance of the ITMS method was evaluated and compared from a double perspective: first, we assessed the ability of ITMS to detect blink-events using synthesized data; and second, we evaluated using real data the effect of suppressing blink-artifacts with ITMS to improve the quality of the CAEP. This section presents the methods and results of these two experiments.

3.1. Subjects

Forty-four normal hearing adults participated in this study (21 males, 44.38 ± 6.95 yr). All participants showed normal hearing sensitivity at test frequencies 0.25, 0.5, 1,
2, 3, 4, 6, and 8 kHz. Hearing thresholds were estimated in 2 dB steps with an Interacoustic AC40 audiometer (Interacoustics A/S, Middelfart, Denmark). All subjects were informed about the test protocol, gave written consent to participate, and were paid at the end of the session to cover trip expenses. From the full set of 44 subjects tested, 14 subjects (7 males, 43.64 ± 7.30 yr) were randomly selected for estimating the predefined blink-artifact template $h_0(n)$ (details in appendix B), and the remaining 30 subjects (14 males, 44.73 ± 6.88 yr) were used in the assessment experiments.

3.2. EEG recording and analysis

The EEG recording protocol consisted of the presentation of auditory stimuli to the subjects and the recording of their associated neural response through surface gold-plated electrodes placed on the high-forehead (active), middle-forehead (ground), and right mastoid (reference). The EEG was recorded using the SmartEP auditory evoked potentials recording system and the Continuous Acquisition Module (SmartEP-CAM, Intelligent Hearing Systems, Miami, FL). The sampling frequency was 1 kHz, the gain of the preamplifier was set at 10,000, and the cut-off frequencies for the bandpass analogue filters were [1-300] Hz. The auditory stimulus consisted of a 170 ms duration /da/ synthesized in Praat [55] with a sampling frequency of 44,100 Hz. The /da/ stimulus was exported to Matlab in order to generate the stimulation sequence, which consisted of 250 repetitions of the /da/ stimulus, presented at 75 dB sound pressure level (SPL), at a fixed rate of 0.66 Hz. Thus, the duration of the sequence was about 380 seconds. The stimulation sequence was delivered monaurally on the right ear through the ER-3A insert earphones (Etymotic Research, Inc., Elk Grove Village, IL), which were connected to a Fireface UCX audio soundcard (RME Audio, Haimhausen, Germany). Stimulus level was calibrated by a type HA2 artificial ear 2-cc acoustic coupler connected to a type 4144 pressure microphone, which was connected to a type 2636 measuring amplifier through a type 2639 preamplifier cable (Brüel & Kjær Sound & Vibration Measurement A/S, Nærum, Denmark). During the EEG recording session, the subjects were lying on a comfortable couch, with their neck and shoulder muscles relaxed, while watching a movie of their choice in silent mode with subtitles. The subjects were asked to keep still during the test and to blink normally. The recording sessions took place in an electromagnetically-shielded booth at the National Acoustic Laboratories (Sydney, Australia). Analysis of recorded signals was carried out by custom scripts developed in Matlab (R2015b), using the Signal Processing and the Statistics and Machine Learning Toolboxes.

This protocol is in accordance with the National Statements on Ethical Conduct in Human Research and was approved by the Macquarie University (Ref 5201400862) and by the Australian Hearing (Ref AHHREC2014-5) Human Research Ethics Committees.
3.3. Experiment 1. Detection of blink-events

3.3.1. Methods  Evaluating detection of blink-events from a single frontal EEG channel is a problem because the position of the blink-events in the EEG is not known. This handicap can be solved using synthesized data. In this experiment, we artificially synthesized a number of EEGs with similar noise characteristics as real EEGs, but with the advantage that the position of the blink-events was known in advance.

The artificial EEGs were synthesized from real EEG data collected in 10 subjects (5 males, 43.70±7.23 yr). These subjects were selected from the subset of 30 subjects for presenting large-amplitude blink-artifacts. In each subject, one EEG was synthesized consisting of noise and 300 blink-events. Each EEG was generated in three SNR conditions by modifying the level of noise with respect to the level of the blink-artifacts (signal). The evaluated SNRs were +10 dB, +5 dB, and 0 dB. The noise distributions of the synthesized EEGs consisted of real EEGs after removing all segments containing suspected blink-events after visual inspection. Visual inspection was repeated at least twice, and the selected EEG segments were joined with a 100 ms cosine-square overlapping. This procedure was followed to ensure that the noise distribution of the synthesized EEGs were similar to those of real EEGs, e.g. similar spectral density, non-stationary time-series, etc. The 300 blink-events of each synthesized EEG corresponded to 30 different blink-artifact waveforms of 1.4 s duration (0.25 s pre- and 1.15 s post-local maximum) extracted from the real EEG, each of them used 10 times. The 300 blink-events were randomized, amplitude-normalized, and distributed to synthesize the artificial EEG. The distribution of the inter-blink-interval (time in milliseconds between the onsets of adjacent blink-events) was a $\sim N(2000, 600)$ distribution, i.e inter-blink-intervals followed a Normal distribution with a mean of 2000 milliseconds and a standard-deviation of 600 milliseconds. The distribution of the blink-event amplitudes $A_k$ followed a $\sim N(55, 14)$ distribution. These parameters approximate the real blink-event distributions observed in the 10 analyzed subjects.

The performance of ITMS in detecting blink-events in synthesized EEGs was compared with MSDW [51], a technique that was specifically conceived to detect blink-events from a prefrontal EEG channel. ITMS was implemented as described in section 2 of this paper, using 3 iterations ($I = 3$). MSDW was implemented using the Matlab toolbox provided by the authors [51]. Unlike ITMS, which includes an automatic procedure to estimate the optimal threshold that separates the noise and the blink-events distributions ($T$), MSDW requires the user to select this threshold manually. We evaluated the performance of MSDW at the threshold suggested by the authors (threshold equal to 130) and at the threshold that we found most appropriate in the tests we did with real EEGs (threshold equal to 80).

The same synthesized EEGs were used in the two techniques for detection purposes. Detection consisted of classifying the blink-events as: true-positive (TP), when the method correctly detected the blink-event; false-negative (FN), when the method did not detect a blink-event; and false-positive (FP), if the method returned a detected
Table 1. True positive rate (TPR) in percentage (%) and false positives per second (FPPS) obtained at different SNRs with the ITMS method evaluated at the automatic threshold \( T \), and with the MSDW method evaluated at the thresholds equal to 80 (MSDW\(_{80}\)) and equal to 130 (MSDW\(_{130}\)).
in the other two cases (low TPR at +10 dB SNR, and high FPPS at 0 dB SNR); and (c) ITMS evaluated at the automatic threshold reaches an adequate compromise between high TPR and low FPPS in the three SNR conditions.

3.4. Experiment 2. Quality improvement of CAEPs

3.4.1. Methods The aim of this experiment was to evaluate the extent in which the ITMS and the MSDW methods improved the quality of cortical auditory evoked potentials (CAEPs) compared to the responses obtained without processing (RAW). The EEGs recorded in 30 normal hearing subjects (14 males, $44.73 \pm 6.88$ yr) were low-pass filtered ($4^{th}$ order Butterworth, 30 Hz), and processed with the ITMS and MSDW techniques. In MSDW, since this method does not allow correction of the blink-artifact (only detection), we obtained the processed EEGs by linear interpolation of the detected blink-events boundaries. We implemented MSDW at the threshold in which best performance was observed (threshold equal to 80). The EEGs processed...
with ITMS corresponded to the $y_{enhanced}(n)$ signals, described in section 2, in which the blink-artifacts were suppressed.

As presented in section 3.2, the recorded EEGs contained the neural responses evoked by 250 /da/ stimuli. In each EEG, we obtained five different CAEP signals by averaging and demeaning five blocks of 50 sweeps (EEG segments corresponding to the first 300 ms from the stimulus onset). The quality of the signals was estimated in terms of their reproducibility by calculating the correlation coefficient ($r$) between all possible combinations of the five CAEPs, taken two at a time (10 statistics per subject) [56]. Thus, we obtained an $r$-distribution of 300 statistics (30 subjects) for the RAW, MSDW, and ITMS scenarios.

Since none of the three $r$-distributions were normally distributed ($p$-values were statistically significant in the Lilliefors normality test), the three $r$-distributions were compared by the non-parametric Kruskal-Wallis analysis of variance test, applying the Tukey-Kramer correction for multiple comparisons. Statistic significance was achieved for $p$-values lower than 0.05 [57].

### 3.4.2. Results

Figure 4.A shows an example of an unprocessed EEG segment (RAW), and processed with the MSDW and ITMS methods. This figure shows that despite both ITMS and MSDW detect all blink-events in this segment, ITMS is better at suppressing the blink-artifact. Since MSDW assumes that the shape of the artifact is triangular [51], the boundaries of the detected blink-events only include the first positive peak of the artifact. In contrast, ITMS characterizes all components of the blink-artifact waveform, and the suppression is more efficient. Figures 4.B-E show the CAEP signals obtained in each scenario in the first four subjects. The CAEP signals are presented overlapped to allow visual inspection of reproducibility. In each subject and condition, the number at the top of the charts show the mean of the correlation coefficients obtained between all possible combinations of CAEP signals taken two at a time (10 statistics). The individual results obtained in the remaining subjects are shown as supporting material in appendix C.

Figure 5 shows the raw distributions (gray-filled circles), the box plots, and the mean and standard error of the mean (errorbars) for the $r$-distributions in each analysed scenario. The box plots show the quartile ranges of the distributions (the notch in the boxes indicating the median). The mean values corresponding to the RAW, MSDW, and ITMS $r$-distributions are, respectively, 0.37, 0.54, and 0.65. The $p$-values shown at the top of the figure are the result of the multiple comparison test derived from the Kruskal-Wallis analysis of variance test. The results of this experiment indicate that: (a) both MSDW and ITMS methods improve the quality of CAEP signals; and (b) ITMS presents a statistically significant greater improvement (0.11 greater $r$-values on average) compared to MSDW.

Figure 6 shows the distributions of the inter-blink interval (IBI) and the amplitude of the blink-events detected in all subjects. This figure shows that on average (estimated as the mean between the first and the third quartile of the distribution), the subjects

4. Discussion

This paper presents in detail and evaluates the performance of the Iterative Template Matching and Suppression (ITMS) technique. This paper shows that (a) ITMS presents an adequate performance in detecting and suppressing blink-artifacts from a single EEG channel; (b) it is fully automatic, since the method does not require any user setup; (c) in contrast to other methods like ICA and DWT, that decompose the EEG signals into a number of components, operate in the transformed domain, and recompose the signals,
ITMS is less invasive, since the blink-artifact correction only occurs in the contaminated EEG segments; and (d) the underlying mathematics are not complex and the method is easy to implement, as a script programmed in Matlab is provided as supplementary material.

ITMS aims to solve two classical limitations of previous methods based on template matching: the selection of the template and the estimate of the threshold. The performance of template matching is highly dependent on the template selection [51]. Previous methods used a library of blink-artifact templates of different waveforms to adapt the inter-subject variability [49, 50], however this approach presented the drawbacks of (a) generating a sufficiently large database of templates, and (b) the selected template would never perfectly match the blink-artifact waveform of the analyzed subjects. In contrast, ITMS solves the problem of template selection through an iterative process. This approach does not require a library of templates, and blink-events detection is performed using a blink-artifact template particular for each analyzed subject.

A second limitation of previously implemented template matching-based methods is that the threshold that separates the blink-events from the noise distribution was selected manually by the user [49, 50], which makes these methods inconsistent worldwide and dependent on human expertise. Moreover, this paper highlights the limitations of methods relying on manual thresholds. Firstly, the MSDW threshold suggested by the authors of this technique (threshold equal to 130) did not work well with our data, since the TPR was extremely low in all SNR scenarios (see table 1). And secondly, we observed that a threshold equal to 80 was the most appropriate in our set of real data, however, figure 3 and table 1 also show that while this threshold was appropriate in the +5 dB SNR scenario, it was not efficient when the SNR was high (low TPR) and when the SNR was low (high FPPS). In contrast, the automatic approach taken by ITMS presented an adequate blink-events detection performance irrespective of the SNR of the test.

This paper also questions the blink-artifact triangular shape assumption considered by some techniques like MSDW. The blink-artifact waveforms observed across subjects in this study presented a similar morphology, consistent with previous studies [60, 61]: an onset with an abrupt peak following a lower frequency component which extends up to 1 second approximately. Figure 4.A shows an EEG segment contaminated by a number of blink-artifacts (RAW) and the same segment corrected by the MSDW and ITMS methods. This figure shows that the triangular-shape assumption of MSDW allows detection of only the onset peak of the artifact, and therefore, the artifact cannot be completely removed. By contrast, the blink-artifact template estimated by ITMS allows an adequate characterization and suppression of the artifact, which leads to a greater improvement of the quality of the signal of interest (figure 5).

Despite MSDW only allowing blink-artifact detection, we implemented a blink-artifact correction procedure consisting of linear interpolation between the boundaries of the detected blink-artifacts. This approach was followed because, despite other
techniques having previously attempted to suppress blink-artifacts in single EEG channel applications, we did not find any alternative satisfactory option. Kanoga and Mitsukura (2014) described a method suppressing from the EEG the frequency components of the blink-events, which are estimated through a 2-step non-negative matrix factorization [60]. However, this method does not allow blink-events detection, and its performance is strongly dependent on the selection of the basis $K_1$ and $K_2$, which requires human intervention and with no procedure available to obtain an optimal selection. Rahman and Othman (2015) aimed to solve the need for an EOG reference channel in adaptive filtering by replacing this channel with a softened version of the EEG using a Savitzky-Golay filter [61]. The problem of using a low-pass version of the EEG as a reference is that relevant low frequency EEG components could be suppressed. Majmudar et al. (2015) and Khatun et al. (2016) presented a similar approach based on the discrete wavelet transform (DWT) [62, 63]. This technique basically consists of three steps: decomposing the EEG into a series of high pass and low pass filters, thresholding the coefficients, and recomposing the signal from the filtered components. The major limitation of DWT is that this technique is not efficient when the artifacts overlap in the frequency domain [21].

Four considerations must be taken into account about ITMS. First, the signal of interest and the blink-artifacts must be decorrelated, otherwise part of the signal of interest could be modeled as artifact and be suppressed from the EEG. This assumption is not valid if the test requires auditory stimuli presented at very loud levels, i.e. greater than 80 dB hearing level (HL), since these sounds may evoke an involuntary contraction of the orbicularis oculi muscle (acoustic startle reflex) [58, 59]. Second, ITMS is able to detect, characterize and suppress the artifact associated with the blink activity, but not other types of artifacts like eye saccades, muscular or cardiac activity. Nevertheless, ITMS could be implemented in conjunction with other denoising techniques. Third, the blink-artifact model $\hat{x}_{\text{blink}}(n)$ generated by ITMS represents the LTI component of the blink-artifact signal $x_{\text{blink}}(n)$, which is unknown. ITMS introduces linear variations in the amplitude of the estimated blink-artifact template to match each blink-artifact detected in the EEG, but it does not perform other non-linear transformations on the template. The results of this study show that removing the LTI component of the blink-artifact signal improves the quality of CAEP signals significantly (figure 5). Finally, since ITMS requires the full EEG to operate, this method can only be applied in offline applications.

Although ITMS is outlined for a single EEG channel application, this method could also be scaled to a multichannel configuration. This setup would involve a first step in which blink-events detection ($m_k$) is carried out from a single frontal channel, as described in this paper; and a second step in which, considering the estimated $m_k$, the blink-artifacts are estimated and suppressed in the remaining EEG channels by applying without any iteration the processes “Template estimation”, “Amplitudes estimation” and “Blink-artifact suppression” (described in section 2). The implementation of ITMS in a multichannel configuration could be approached in a future study.
